

## 0.1 ls.net: Network Least Squares Regression for Continuous Proximity Matrix Dependent Variables

Use network least squares regression analysis to estimate the best linear predictor when the dependent variable is a continuously-valued proximity matrix (a.k.a. sociomatrices, adjacency matrices, or matrix representations of directed graphs).

### Syntax

```
> z.out <- zelig(y ~ x1 + x2, model = "ls.net", data = mydata)
> x.out <- setx(z.out)
> s.out <- sim(z.out, x = x.out)
```

### Examples

#### 1. Basic Example with First Differences

Load sample data and format it for social networkx analysis:

```
> data(sna.ex)
```

Estimate model:

```
> z.out <- zelig(Var1 ~ Var2 + Var3 + Var4, model = "ls.net", data = sna.ex)
```

Summarize regression results:

```
> summary(z.out)
```

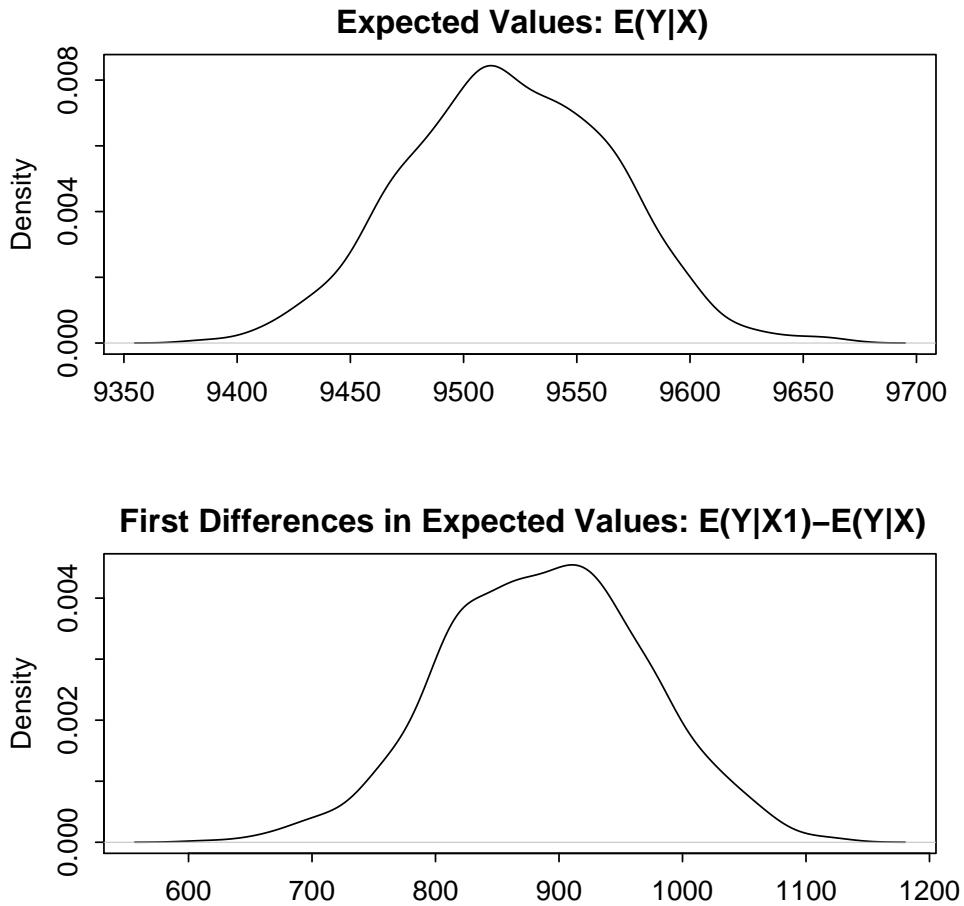

Set explanatory variables to their default (mean/mode) values, with high (80th percentile) and low (20th percentile) for the second explanatory variable (Var3).

```
> x.high <- setx(z.out, Var3 = quantile(sna.ex$Var3, 0.8))
> x.low <- setx(z.out, Var3 = quantile(sna.ex$Var3, 0.2))
```

Generate first differences for the effect of high versus low values of Var3 on the outcome variable.

```
> try(s.out <- sim(z.out, x = x.high, x1 = x.low))
> try(summary(s.out))
```

```
> plot(s.out)
```

## Model

The `ls.net` model performs a least squares regression of the sociomatrix  $\mathbf{Y}$ , a  $m \times m$  matrix representing network ties, on a set of sociomatrices  $\mathbf{X}$ . This network regression model is a directly analogue to standard least squares regression element-wise on the appropriately vectorized matrices. Sociomatrices are vectorized by creating  $Y$ , an  $m^2 \times 1$  vector to represent the sociomatrix. The vectorization which produces the  $Y$  vector from the  $\mathbf{Y}$  matrix is preformed by simple row-concatenation of  $\mathbf{Y}$ . For example if  $\mathbf{Y}$  is a  $15 \times 15$  matrix, the  $\mathbf{Y}_{1,1}$  element is the first element of  $Y$ , and the  $\mathbf{Y}_{21}$  element is the second element of  $Y$  and so on. Once the input matrices are vectorized, standard least squares regression is performed. As such:

- The *stochastic component* is described by a density with mean  $\mu_i$  and the common variance  $\sigma^2$

$$Y_i \sim f(y_i | \mu_i, \sigma^2).$$

- The *systematic component* models the conditional mean as

$$\mu_i = x_i \beta$$

where  $x_i$  is the vector of covariates, and  $\beta$  is the vector of coefficients.

The least squares estimator is the best linear predictor of a dependent variable given  $x_i$ , and minimizes the sum of squared errors  $\sum_{i=1}^n (Y_i - x_i \beta)^2$ .

## Quantities of Interest

The quantities of interest for the network least squares regression are the same as those for the standard least squares regression.

- The expected value (`qi$ev`) is the mean of simulations from the stochastic component,

$$E(Y) = x_i \beta,$$

given a draw of  $\beta$  from its sampling distribution.

- The first difference (`qi$fd`) is:

$$FD = E(Y|x_1) - E(Y|x)$$

## Output Values

The output of each Zelig command contains useful information which you may view. For example, you run `z.out <- zelig(y ~ x, model="ls.net", data)`, then you may examine the available information in `z.out` by using `names(z.out)`, see the coefficients by using `z.out$coefficients`, and a default summary of information through `summary(z.out)`. Other elements available through the `$` operator are listed below.

- From the `zelig()` output stored in `z.out`, you may extract:

- `coefficients`: parameter estimates for the explanatory variables.
- `fitted.values`: the vector of fitted values for the explanatory variables.
- `residuals`: the working residuals in the final iteration of the IWLS fit.
- `df.residual`: the residual degrees of freedom.
- `zelig.data`: the input data frame if `save.data = TRUE`

- From `summary(z.out)`, you may extract:

- `mod.coefficients`: the parameter estimates with their associated standard errors, *p*-values, and *t* statistics.

$$\hat{\beta} = \left( \sum_{i=1}^n x_i' x_i \right)^{-1} \sum x_i y_i$$

- **sigma**: the square root of the estimate variance of the random error  $\varepsilon$ :

$$\hat{\sigma} = \frac{\sum(Y_i - x_i\hat{\beta})^2}{n - k}$$

- **r.squared**: the fraction of the variance explained by the model.

$$R^2 = 1 - \frac{\sum(Y_i - x_i\hat{\beta})^2}{\sum(y_i - \bar{y})^2}$$

- **adj.r.squared**: the above  $R^2$  statistic, penalizing for an increased number of explanatory variables.
- **cov.unscaled**: a  $k \times k$  matrix of unscaled covariances.

- From the **sim()** output stored in **s.out**, you may extract:

- **qi\$ev**: the simulated expected values for the specified values of **x**.
- **qi\$fd**: the simulated first differences (or differences in expected values) for the specified values of **x** and **x1**.
